Abstract—In this paper, we are interested in modeling the diffusion of information in a multilayer network of agents using a thermodynamic diffusion approach. The state of each agent is viewed as a topic mixture, to describe his/her resources, and represented by a distribution over multiple topics. We observe and learn diffusion-related thermodynamical patterns in the training data set, and we use the estimated diffusion structure to predict the future states of the agents. With a priori knowledge of a fraction of the state of all agents, the problem is shown to turn into a Kalman predictor problem that refines the predicted system states using the estimation error of the agents’ states. A real world Twitter data set is then used to evaluate and validate our information diffusion model.

Index Terms—Multilayer networks, Kalman-Bucy filter, predictor, diffusion network.

I. INTRODUCTION

Different topics are discussed/diffused in social networks and because of the distinct dynamics of these diffusions, agents in the social networks are affected differently. The temporal and spatial dynamics of diffusion have been studied through sequences of activation nodes and observed as spreading cascades in a network [9].

The information diffusion process models can be classified into three major groups, probabilistic models, thermodynamic models, and counting models. NETINF [7], NETRATE [16] and INFOPATH [8] are the probabilistic models which infer the underlying diffusion network among information sources using consecutive hit times of the nodes by a specific cascade. The main idea behind the thermodynamic models [5,6,13,18] is that heat will propagate from a warmer region to a colder region, or gas will move from the region with higher density to the region with lower density. Modeling the information as heat or gas, we can write the rate at which information is changing in agent \(i\) as: \(\frac{d\psi_i}{dt} = D \sum_j A(i,j)(\psi_j - \psi_i)\), \(\psi_i(t)\) is the state of the \(i^{th}\) agent at time \(t\), \(D\) is the diffusion constant which reflects the amount of information passing from one agent to another agent in a small interval of time, and \(A(i,j)\) is the \((i,j)\) element of adjacency matrix. The counting models [10] form counting processes to find the number of nodes in each group of susceptible or infected nodes. SIS [12] and SIR [17] are two well-known models in this group.

One central challenge in modeling information diffusion is to understand the structure of the cascade; the existence of unknown external influence factors and unclear graph connections obscures this query. In this paper, we propose for the first time to model the simple diffusion on a general multilayer network, and apply the model to publication networks and social media data.

The multilayer network connectivity structure has been proposed and studied in [1,3,4,14,15], in particular, a two-layer network was studied in [6] under the Laplacian dynamics. The information flow following a Laplacian process on a multilayer network in its most general form, has however, yet to be studied. A multilayer network (illustrated in Fig.1) takes into consideration additional connection criteria when the true connections among the agents are uncertain. For example, social media such as blogs consist of a set of documents generated by bloggers over time; these documents may share some topical similarities despite of their different sources. It is possible to structure the document similarities into a relational property as a network of documents. One can then further associate this connectivity layer with the connection of bloggers (e.g., according to following-follower connection). This leads to a multilayer network model where information diffuses both within a single layer and across layers. The additional paths due to the multilayer structure, diffuse the information at a secondary degree, specifically, an absence of a direct connection between two bloggers may be reestablished by counting the topical similarities between the documents they are associated with. We will refer to the resulting network from a multilayer construction as an interconnected network of heterogeneous nodes.

In a community-like network of agents with common interest, such as a network of authors with their publications, online forum community, we have observed diffusion related thermodynamical patterns. It turns out that the simple diffusion model on the interconnected network structure is very effective in predicting the future states of the agents.

The paper is organized as follows: We propose our new approach in Section II, and present substantiating experimental results in Section III. We finally provide the concluding remarks in Section IV.

II. THE PROPOSED METHOD

In closed systems, all changes in the agents’ states are a result of interaction among the agents in the network. In a single layer network, a diffusion process based on the heat equation has been studied in [5,6,13,18]. Independently of the nodes in a multilayer network be agents or documents, we generalize the single layer diffusion process to:

\[
\frac{dX}{dt} = -LX. \tag{1}
\]
Where $X$ is a $N \times T$ matrix, $N$ being the number of nodes in a multilayer network, and each row of $X$ is a $T$-dimensional state vector for each node. $L$ is a $N \times N$ supra-Laplacian matrix defined in proposition (1).

**Proposition 1.** We can generally write the supra-Laplacian matrix of an $M$ multilayer network with $N$ nodes in each layer as Eqn. (2). Where $L_{\alpha}$ is the supra-Laplacian matrix of the intra-layer connectivity and $L_I$ is the supra-Laplacian matrix of the inter-layer connectivity. $L_L$ may be in turn, written as direct sum of the Laplacian matrices of the independent intra-layer connectivities:

$$L = L_{\alpha} + L_I,$$

$$L_L = \bigoplus_{\alpha=1}^M D^{(i)}(\alpha)L^{(\alpha)} = \begin{bmatrix} D^{(1)}(\alpha)L^{(1)} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & D^{(M)}(\alpha)L^{(M)} \end{bmatrix}$$

The $D^{(i)}$ is the intra-layer diffusion constant of nodes in layer $i$, and $L^{(\alpha)}$ is the Laplacian matrix of the intra-layer connectivity of layer $\alpha$. The inter-layer supra-Laplacian can be written as $L_I = \sum_{\alpha=1}^M (K_{\alpha}^i - W_{\alpha}^i)$, where the $K_{\alpha}^i$ is the diagonal inter-layer degree matrix of layer $\alpha$, showing the inter-layer degree of the nodes in layer $\alpha$ and the $W_{\alpha}^i$ is the inter-layer connectivity matrix of the nodes in layer $\alpha$ with the nodes in the other layers. The $K_{\alpha}^i$ and $W_{\alpha}^i$ are formally defined in Eqns. (4 and 5) respectively:

$$K_{\alpha}^i = e_{(\alpha,\alpha)} \otimes \left( \sum_{\beta=1, \beta \neq \alpha}^M D^{(\alpha,\beta)} K^{(\alpha,\beta)} \right),$$

$$W_{\alpha}^i = \sum_{\beta=1, \beta \neq \alpha}^M (e_{(\alpha,\beta)} \otimes (D^{(\alpha,\beta)} W^{(\alpha,\beta)}),$$

where $D^{(\alpha,\beta)}$ is the inter-layer diffusion constant of agents from layer $\alpha$ to agents in layer $\beta$, $K^{(\alpha,\beta)}$ is the diagonal matrix reflecting the degree of each node in the inter-layer connectivity between layer $\alpha$ and layer $\beta$, $W^{(\alpha,\beta)}$ quantifies the inter-layer connectivity of the layer $\alpha$ nodes to the layer $\beta$ nodes and $e_{(\alpha,\beta)}$ is an all 0, $M \times M$, matrix with an only 1 element in $(\alpha, \beta)$, $\otimes$ denotes the kronecker product.

The proof of proposition (1) can be found in the extended version of the paper [11].

Much of the existing work in information diffusion models have a limited scope (of agents, documents, parameters) when predicting the future state of the nodes. More specifically, agent states may be varied by external sources which are not captured in the network, or by some agents actions which may even to some extent, conflict with the model prediction. Considering an interconnected network with a supra-Laplacian matrix $L$, we address the additional auxiliary input, thus generalizing Eqn. (1) to an open system model as follows:

$$dX(t) = -LX(t)dt + \Sigma dB(t).$$

$B(t)$ is a $T \times T$ matrix, whose columns are $T$-dimensional vectors with components as independent standard Brownian motions of variances $\sigma_i$, and $\Sigma$ is $N \times T$ matrix, and each row shows the $\sigma_i$ vector for agent $i$. Inspired by the Ornstein-Uhlenbeck (O.U.) process [19], Eqn. (6) describes the velocity of the topical-state of the nodes as a Brownian motion in presence of friction. In other words, to describe the uncertainty due to external effects, we proceed to view the whole system as a massive Brownian particle. The drift term (first term in right-hand side of Eqn. (6)), however, moves the velocity from a martingale state of $\sigma_i dB(t)$ towards a consensus (captured by the drift term). The solution of the differential equation in Eqn. (6), can be expressed as follows: given the states of nodes at time $t_0$ we can predict the states at time $t_1$ , $t_1 > t_0$ as follows:

$$\tilde{X}(t_1) = e^{-L(t_1-t_0)}X(t_0) + \int_{t_0}^{t_1} e^{L(s-t_1+t_0)} \Sigma dB(s),$$

where $e^{L(s-t_1+t_0)}$ is a matrix exponential of a $N \times N$ size.

Our proposed learning procedure aims at determining the diffusion constants in the supra-Laplacian matrix $L$ as well as the $\Sigma$ matrix. To that end, we proceed to minimize the
Frobenius norm of the difference between \( \mathbf{X} \) and its predicted \( \hat{\mathbf{X}} \),

\[
\arg\min_{\mathbf{X}, \delta_1,...} g = \| \mathbf{X}(t_1) - \hat{\mathbf{X}}(t_1) \|_F.
\]

(8)

Solving this optimization problem helps us decompose the predicted matrix into two main components on the right-hand side of Eqn. (7), the first term representing the interactions in the network, while the second quantifying the uncertainty which results from auxiliary inputs into the system.

A. Diffusion Network Estimation (Learning the Supra-Laplacian Matrix)

The supra-Laplacian matrix \( \mathcal{L} \) which we use in Eqn. (6) for state prediction, is the result of the network connectivity (refer to Eqn. (2)). In practice, hidden connections are pervasive, introducing uncertainty in the prediction, and thus requiring additional explicit connections for the information diffusion. To that end, consider observations of \( \mathbf{X}(t) \) over \( t \in [0, t_1] \), and denote \( \bar{\mathbf{x}}(t) := \text{vec}(\mathbf{X}(t)) \), the vectorization of \( \mathbf{X}(t) \) to obtain a vector differential system in order to learn the supra-Laplacian matrix \( \mathcal{L} \) of Eqn. (6):

\[
\dot{\bar{\mathbf{x}}}(t) = \Lambda \bar{\mathbf{x}}(t) + \mathbf{w}(t), \quad 0 \leq t \leq t_1,
\]

where \( \Lambda = \mathbf{I}_T \otimes (-\mathcal{L}) \), the Kronecker product of \( T \)-by-\( T \) identity matrix with \( (-\mathcal{L}) \) and \( \mathbf{w}(t) \) is the vectorization of \( \mathbf{w}(t) = \Sigma \frac{d\mathbf{h}(t)}{dt} \).

To that end, the simple cost functional \( J = \frac{1}{2} \mathbf{e}^T \mathbf{e} \), where \( \mathbf{e} = \mathbf{x} - \hat{\mathbf{x}} \), and estimating \( \hat{\Lambda} \) we have \( \hat{\Lambda} = \gamma(\mathbf{x} - \hat{\mathbf{x}}) \mathbf{x}^T \) (derivative of \( J \) with respect to \( \hat{\mathbf{x}} \)), where the estimation \( \hat{\mathbf{x}}(t+1) = \mathbf{e}^T \hat{\mathbf{x}}(t) \), and \( \gamma > 0 \) is appropriately chosen as the scaling gain. In optimization iterations, the estimated value of \( \hat{\Lambda} \) at the \( i^{th} \) iteration is as follows:

\[
\hat{\Lambda}_i = \hat{\Lambda}_{i-1} + \hat{\Lambda}_{i-1}.
\]

We use \( \hat{\Lambda}_0 = \mathbf{I}_T \otimes (-\mathcal{L}) \), the graph Laplacian of the explicit following-follower network (as initialization). The learned \( \hat{\Lambda} \) may, however, not be exactly structured as \( \mathbf{I}_T \otimes (-\mathcal{L}) \), due to dependence of topics in the state space, as well as the nonlinearity and non-homogeneity of the diffusion. The resulting error \( \mathbf{e} \) shall be considered for the estimation of the noise in the Kalman-Bucy filter as discussed next.

B. A Refined Prediction: Kalman-Bucy Filtering

In prediction applications, the actual states of some of the nodes are sometimes known, and we want to predict those of all remaining nodes. An example of this may be seen in social networks, where states of the hub nodes, such as famous people or users with less restrictive privacy policies are known to the public, and one is interested in predicting the states of other less accessible users. Having partial knowledge of the states of a fraction of the nodes in the network, changes the state prediction problem to a Kalman predictor problem, and helps to refine the predicted states using a Kalman filter. We propose a Kalman-Bucy filter as the optimal linear predictor for our system, and write the observation equation as \( \mathbf{y}(t) = (\mathbf{I}_T \otimes \mathbf{H}) \mathbf{x}(t) + \mathbf{v}(t) \), with \( \mathbf{H} \) as a diagonal indicator matrix with 1 in all the observed entries, and 0 in all other entries. \( \hat{\mathbf{x}} \) having been learned (see above Section), Kalman-Bucy equations may be written as:

\[
\dot{\hat{\mathbf{x}}}(t) = \hat{\Lambda} \hat{\mathbf{x}}(t) + \mathbf{w}(t),
\]

(9)

\[
\hat{\mathbf{y}}(t) = \mathcal{H}\hat{\mathbf{x}}(t) + \mathbf{v}(t),
\]

(10)

where \( \mathcal{H} = \mathbf{I}_T \otimes \mathbf{H} \) and the noises \( \mathbf{w}(t) \) and \( \mathbf{v}(t) \) are zero-mean white (temporally) processes, i.e., \( E(\mathbf{w}(t)\mathbf{w}(s)^T) = \mathbf{Q}_t \delta(t-s) \), \( E(\mathbf{v}(t)\mathbf{v}(s)^T) = \mathbf{R}_t \delta(t-s) \), \( E(\mathbf{w}(t)\mathbf{v}(s)^T) = 0 \). By considering small time intervals in the discretization of the linear continuous time system \( \delta_t = 1 \), one can write the state equation as \( \hat{\mathbf{x}}(t+1) = \mathbf{F}(t)\hat{\mathbf{x}}(t) + \mathbf{w}(t) \), where \( \mathbf{F} = \mathbf{I} + \hat{\Lambda} \).

Having Eqn. (10) and \( \hat{\mathbf{x}}(t+1) = \mathbf{F}\hat{\mathbf{x}}(t) + \mathbf{w}(t) \) as the state and observation equations respectively, we can predict and refine the predicted states of the nodes using Algorithm (1). The "learning phase" of Algorithm (1) is estimating the supra-

Algorithm 1

Learning phase:

1: \( \bar{\mathbf{x}}(t) \leftarrow \text{vec}(\mathbf{X}(t)) \)
2: \( \Lambda \leftarrow \mathbf{I}_T \otimes (-\mathcal{L}) \) \( \triangleright \) Initial state.
3: repeat:
4: \( \bar{\mathbf{x}}(t+1) \leftarrow e^T \hat{\mathbf{x}}(t) \)
5: \( \hat{\Lambda} \leftarrow \gamma(\bar{\mathbf{x}} - \bar{\mathbf{x}}) \bar{\mathbf{x}}^T \)
6: \( \hat{\Lambda} \leftarrow \hat{\Lambda} + \hat{\Lambda} \)
7: until \( ||\bar{\mathbf{x}} - \bar{\mathbf{x}}||_2 < \eta. \) \( \triangleright \) Convergence criteria.

Kalman filter prediction on test data:

1: \( \mathbf{R}_{t,t} \leftarrow \mathbf{R}_t + \mathcal{H}\Pi_{t-1,t} \mathcal{H}^T \) \( \triangleright \) Updating.
2: \( \bar{\mathbf{x}}_{t+1,t} \leftarrow \bar{\mathbf{x}}_{t+1,t} + \Pi_{t-1,t} \mathcal{H}^T \mathbf{R}_{t+1,t}^{-1}[\hat{\mathbf{y}}_{t+1,t} - \mathcal{H}\hat{\mathbf{x}}_{t+1,t}] \)
3: \( \Pi_{t+1,t} \leftarrow \Pi_{t+1,t-1} - \Pi_{t+1,t-1} \mathcal{H}^T \mathbf{R}_{t+1,t}^{-1} \mathcal{H} \Pi_{t-1,t} \)
4: \( \hat{\mathbf{F}} \leftarrow \mathbf{I} + \hat{\Lambda} \)
5: \( \bar{\mathbf{x}}_{t+1,t} \leftarrow \mathbf{F}\hat{\mathbf{x}}_{t+1,t} \) \( \triangleright \) Predicting.
6: \( \Pi_{t+1,t} \leftarrow F\Pi_{t,t} F^T + \mathbf{Q}_t \)

Laplacian matrix \( \hat{\Lambda} \) (see above Section). The second phase of the algorithm, is refining the estimated state of the nodes. Note that \( \mathbf{R}_t \) is the covariance of the observational error, and \( \hat{\mathbf{x}}_{t+1,t|t} \) denotes the linear prediction of \( \mathbf{x} \) at time \( t_2 \) given observations up to and including time \( t_1 \). The state covariance \( \Pi_t \) satisfies the Riccati equation:

\[
\Pi_t = \hat{\Pi}_t + \Pi_t \hat{\Lambda}^T + \mathbf{Q}_t - \mathbf{G}_t \mathbf{R}_t \mathbf{G}_t^T.
\]

(11)

While the \( \mathbf{G}_t \) is the Kalman gain \( \mathbf{G}_t = \Pi_t \mathcal{H}^T \mathbf{R}_{t}^{-1} \). For simplicity, we further assumed that the errors in the state prediction and observation are Gaussian processes.

The designed algorithm shows the discrete time, state update of the Kalman predictor. The estimated states of the available nodes, \( \mathcal{H}\hat{\mathbf{x}}(t) \), are compared with the state of the available nodes, \( \tilde{\mathbf{y}}(t) \), as measurements observed over time, to evaluate the extent of statistical noise and other inaccuracies in predicting phase.
Fig. 2: (a) Experiment for college professor network with 1000 publication documents. (b) Experiment over Twitter network with 5000 agents and 8 Hashtags.

III. EXPERIMENTS

Fig. (2a) shows the prediction based on a network of 79 researchers. A three-layer network is formed with the first layer showing if two researchers have ever published in the same venue or not. The second layer being the research group membership of these researchers and the third layer showing the similarity network between the published papers (extracted by LDA [2] topic modeling of the abstract of the papers with dimension 10). The states of the agents are 10-dimensional topical vectors which are the mean of the topical representation of the documents produced by the agents. Over time, more documents are getting added and the topical states of agents are changing. The error measure used in all the experiments is the Frobenius norm of the difference of the estimated states of the nodes and ground truth states of the nodes normalized by the Frobenius norm of the ground truth matrix. As may be seen in Fig. (2a), the prediction method based on a three-layer network achieves a lower error than the prediction based on a single-layer network. Note, the single-layer network does not help in predicting the topical states of the agents. The reason is that there are only 79 agents in this experiment, and the co-authorship network between the agents is not particularly suited to predict the future state of the agents.

Fig. (2b) is an experiment based on 5000 Twitter users. The first layer is a network among users and the second layer is a network between eight Hashtags used in June 2009. The Hashtags are as follows: #jobs, #spymaster, #heda, #140mafia, #tcot, #musicmonday, #franelection, #iremember. These show the similarities of the Hashtags by counting and normalizing the number of times they have appeared in the same tweet. The average prediction improvement achieved by the two-layer network is about 13 percent. The prediction by first estimating the Laplacian matrix, shows 15 percent improvement over the single layer prediction method.

Fig. (3) displays the results of an experiment in a small single layer dataset with 300 Twitter agents available. Figs. (3a), (3b), (3c) and (3d) are the same experiments with different observation sizes of 10 percent, 15 percent, 20 percent and 25 percent of states of all the agents in the network respectively. As may be seen in the figures, the prediction error based on the estimated Laplacian matrix yields a lower error than fully trusting the connectivity structure in the network. This as expected, is due to static connectivity network (usually demonstrates the physical or online relation among the agents), falling short on affecting the actual underlying diffusion structure on the network. Having a prior partial knowledge of the agents enabled us to use a Kalman predictor to further refine our prediction.

IV. CONCLUSIONS

In this paper, we proposed a technique to model and predict node states in a multilayer network. The actual diffusion network was learned by looking at previous diffusion data and applied to predicting the future states of agents in the network. Having partial observation of the state of the agents changes the state-space dynamics model to a Kalman filter problem. The Kalman filter allows us to further refine our state prediction by learning over the prediction error of the observed subset. In future work, we will explore the information diffusion problem with a goal to develop necessary tools to analyze diffusion in more complex network structures.
